## Abstract

---

The effect of various impurities and micro-alloying additions (B, N, C, O, Al, Si, S, and P) on the intrinsic resistance of the  $\Sigma 3$  (111) grain boundary in tungsten has been investigated using the molecular dynamics simulation. The atomic interactions have been accounted for through the use of Finnis-Sinclair interatomic potentials. The fracture resistance of the grain boundary has been characterized by computing, in each case, the ideal work of grain boundary separation, the mode I stress intensity factor, and the Eshelby's  $F_1$  conservation integral at the onset of crack propagation. The results obtained suggest that pure tungsten is relatively resistant to grain boundary decohesion and that this resistance is further enhanced by the presence of B, C, and N. Elements such as O, Al, and Si, however, have a relatively minor effect on the cohesion strength of the  $\Sigma 3$  (111) grain boundary. In sharp contrast, S and P greatly reduce this strength, making the tungsten quite brittle. These findings have been correlated with the effect of the impurity atoms on material evolution at the crack tip.

## **Acknowledgments**

The work was supported by the U.S. Army Research Office (ARO), Grant DAAH04-96-1-0917, and by the National Science Foundation (NSF) under Grants DMR-9317804 and CMS-9531930, as well as U.S. Army Research Laboratory (ARL), Weapons and Materials Research Directorate (WMRD) mission funds. The authors are indebted to Dr. Wilbur C. Simmons of ARO and to Drs. Bruce MacDonald and William A. Spitzig of NSF for the continuing interest in the present work. Helpful discussions with Mr. Shugang Lai are greatly appreciated.

INTENTIONALLY LEFT BLANK.

# 1. Introduction

Due to their high density and strength, tungsten (W)-based alloys are widely used in Army systems, especially for antiarmor applications. However, technically pure W is extremely brittle and its ductile→brittle transition temperature (DBTT) is typically as high as 300° C. To overcome the problems associated with the limited toughness of W, the so-called W heavy alloys (WHAs) have been developed [1]. Manufactured by liquid phase sintering, these alloys are actually metal matrix composites consisting of hard W particles embedded in a relatively mild nickel-iron (Ni-Fe) matrix. Although the density of WHAs is only slightly lower than that of pure W, the alloys' antiarmor performance is quite inferior relative to that of depleted uranium, a competing antiarmor material. This difference is related to the fact that, while a depleted uranium penetrator develops adiabatic shear bands upon impact, which give rise to a "self-sharpening" effect [2], the WHA penetrators "mushroom," which leads to an effective increase in the penetrator diameter and, in turn, to a reduction in the depth of penetration. Owing to the well-known environmental problems associated with using depleted uranium, significant resources are currently being directed toward developing WHAs with improved adiabatic shear band behavior. The usual approach is to significantly modify, or find an alternative to, the Ni-Fe matrix.

A different approach has recently been initiated by Krasko [3], who suggested microalloying as a way of obtaining a "ductile" W. Being a body-centered cubic (bcc) metal, such W is expected to acquire the necessary adiabatic shear band behavior since the latter has already been observed in high-strength bcc steels in conditions of "marginal" ductility [4].

The reduced cohesion of grain boundaries is frequently cited as a major factor limiting ductility and, in turn, the performance and reliability of high-strength metallic materials [5, 6]. Intergranular embrittlement in metals is usually caused by impurities segregating to the grain boundaries. Impurities present in bulk concentrations of only 10–100 parts per million (ppm) can result in a dramatic decrease in the mechanical properties (primarily ductility, fracture toughness, and fracture strength) of metallic materials and, thus, pose significant processing and application problems. This detrimental effect of mere parts per million amounts of impurities is

consistent with the fact that only a few parts per million of impurities are sufficient to saturate all the grain boundaries in a polycrystal of the typical grain size (10–100  $\mu\text{m}$ ) [3]. The sensitivity of DBTT to the grain size confirms the aforementioned effect of grain boundary impurities. That is, the smaller the grain size, the larger the amount of impurities required to saturate the grain boundaries at a given temperature; hence, at the same bulk concentration of impurities, higher toughness levels and the lower DBTT are expected in fine-grained polycrystals.

In addition to the smaller grain size, increasing the purity of the metallic system, in general, increases the material's ductility and lowers its DBTT. For example, the DBTT in high-purity W single crystals processed by electron-beam zone remelting, involving the use of a special impurity gettering procedure, was found to be as low as  $-196^\circ\text{C}$ . If impurities are the main cause of embrittlement in W, gettering the impurities is the obvious way of ductilizing this metal. A well-known, though extremely expensive, purity enhanced procedure is the so-called "rhenium effect" [7, 8]. While the actual mechanism of the rhenium effect is not yet completely understood, it is believed to be based on the gettering of oxygen [7, 8]. A more promising way of removing "harmful" impurities, such as O, N, P, etc., from the grain boundary is by gettering them with microalloying additions of selected elements, e.g., B, which leads to the formation of compounds such as boron oxides, boron nitrides, etc. [9–11]. This process, however, requires a careful control of the material chemistry since ductility improvements due to impurity gettering can be expected only when the resulting compound precipitates remain fine. Any coagulation and coarsening of the precipitates generally results in an adverse embrittling effect.

Using both semiempirical and first-principles calculations, Krasko [3] carried out a theoretical analysis of clean W grain boundaries and grain boundaries containing various impurities. His work provided some important results regarding the effect of various grain boundary impurities and microalloying additions. For instance, impurities such as H, N, O, P, S, and Si are found to weaken the intergranular cohesion in W. On the contrary, the presence of B and C was found to enhance the bonding across the grain boundary, thus improving the intergranular cohesion. Furthermore, the so-called site-competition effect, where the species with a lower energy at the grain boundary tend to replace the species that have a higher energy at the grain boundary, was found to play an important role in affecting the impurity distribution at

the W grain boundaries [3]. Among the atomic species analyzed, B was found to have the lowest energy at the grain boundary and thus would tend to displace other impurity atoms from the grain boundary, while at the same time enhancing the intergranular cohesion. Based on these findings, microalloying of technically pure W with 10–50 ppm of B, was recommended as a way of enhancing the ductility of this metal [3]. Experimental investigation of W alloyed with B in amounts 15 times higher than the one recommended by Krasko [3] was found to result in a significant (150° C) drop in the DBTT [9–11]. Microstructural analysis further revealed the presence of relatively coarse boron oxide particles, which are the result of the excessive amount of B in the W. This suggests that the addition of 10–50 ppm of B, which is sufficient to completely displace oxygen from the grain boundaries via the “site competition” effect without an excessive formation of boron oxide, as suggested by Krasko, may result in even higher levels of ductility and fracture toughness.

In the present work, the molecular dynamics method was used to explore the effect of impurities and microalloying additions (B, C, N, O, Al, S, Si, P) on the fracture resistance of the  $\Sigma 3$  (111) grain boundary in W. The organization of this report is as follows. Modifications of the “environment-sensitive embedding” (ESE) energy functions for various grain boundary impurities in W are discussed below. Generation of the computational crystal containing a crack along the  $\Sigma 3$  (111) grain boundary is presented in the section “Computational Crystal.” Computations of the ideal work of grain boundary separation and the  $F_1$  conservation integral are discussed in the next two sections, respectively. The section “Results and Discussion” contains the results obtained in the present study, while the main conclusions are drawn in the final section.

## 2. Procedure

**2.1 Modification of the Finnis-Sinclair Functions for W.** Within the embedded atom model (EAM) formalism [12, 13], the total potential energy of the system is given as the sum of two energy contributions, the interaction of each atom with the local electron density associated with the remaining atoms in the system, called the embedded energy, and a pair-wise interaction

term reflecting the electrostatic interactions between the atoms. In particular, the total potential energy is written as:

$$E_{\text{tot}} = \sum_i F_i(\rho_i) + \frac{1}{2} \sum_{i,j,i \neq j} \phi_{ij}(R_{ij}), \quad (1)$$

where  $F_i$  is the embedded energy of atom  $i$ ,  $\rho_i$  is the electron density at atom  $i$ , and  $\phi_{ij}(R_{ij})$  is the pair-wise interaction between atoms  $i$  and  $j$  separated by the distance  $R_{ij}$ . The electron density at each site is computed from the superposition of spherically averaged atomic electron densities as:

$$\rho_i = \sum_{j \neq i} \rho_j^\alpha(R_{ij}). \quad (2)$$

$\rho_j^\alpha(R_{ij})$  in equation (2) represents the atomic electron density at site  $i$  due to an atom at site  $j$  at a distance  $R_{ij}$ . The superscript  $\alpha$  in  $\rho_j^\alpha(R_{ij})$  is used to specify the species of the atom at site  $j$ . The embedding energies and pair-wise interaction functions in equation (1) are generally determined by fitting various physical quantities of the material such as the sublimation energy, the equilibrium lattice parameters, the second-order elastic constants, the various defect formation energies, and the zero-temperature equation of state [14].

The Finnis-Sinclair method [15] that is usually called "the N-body potential approach" has a slightly different foundation, but the total potential energy can still be expressed in the form of equation (1). The first term, however, has a different meaning since it originates from the tight-binding theory according to which:

$$F(\rho_i) = -A\sqrt{\rho_i}, \quad (3)$$

where  $A$  is a species-dependent parameter whose value for W (1.896373 eV) was determined by Finnis and Sinclair [15] and  $\rho_i$  now represents an environment-dependent effective atomic coordination number, or an effective atomic density at site  $i$ . Finnis and Sinclair [15] originally proposed the following functional form for  $\rho_i$ :

$$\rho_i^h(R_{ij}) = (R_{ij} - R_{\text{cut}})^2, \text{ for } R_{ij} \leq R_{\text{cut}},$$

and

$$\rho_i^h(R_{ij}) = 0, \quad \text{for } R_{ij} > R_{\text{cut}}, \quad (4)$$

where the superscript h stands for "host atoms." For W, Finnis and Sinclair set the cutoff distance  $R_{\text{cut}}$  to a value of 4.400224 Å. Finnis and Sinclair [15] further proposed the following form for the pair-wise potential function  $\phi_{ij}$ :

$$\phi_{ij}(R_{ij}) = (R_{ij} - c)^2 (c_0 + c_1 R_{ij} + c_2 R_{ij}^2), \quad \text{for } R_{ij} \leq c,$$

and

$$\phi_{ij}(R_{ij}) = 0, \quad \text{for } R_{ij} > c, \quad (5)$$

where, for W, the cutoff distance  $c$  is set to a value of 3.4 Å, and the quadratic polynomial coefficients are  $c_0 = 47.13465$ ,  $c_1 = -33.7665655$ , and  $c_2 = 6.254199$ . For W containing interstitial impurities, Krasko [3] introduced a modified Finnis-Sinclair formulation by simply adding a term to equation (1) to account for the energy of impurity atoms in the host environment. The modified  $E_{\text{tot}}$  is then written as:

$$E_{\text{tot}} = \sum_i F(\rho_i^h) + \frac{1}{2} \sum_{i,j} \phi_{i,j}(R_{ij}) + \sum_k ESE(\rho_k^{\text{imp}}), \quad (6)$$

where the first two terms on the right-hand side of equation (6) are given by equations (3)–(5), while the third term represents the sum of the ESE energies of the impurity atoms and is equal to the interaction energy between the impurity and host atoms and  $\rho_k^{\text{imp}}$  is the electron density at the site of impurity atom  $k$  due to the surrounding host atoms and is given as:

$$\rho_k^{\text{imp}} = \sum_j \rho_j^h = \sum_j \rho_j^h(R_{kj}), \quad (7)$$

where  $\rho_j^h(R_{ij})$  represents the electron density defined by equation (4) at the site  $k$  of an impurity

atom due to the host atom at site  $j$ , while  $R_{kj}$  is the distance between the impurity atom at site  $k$  and a host atom at site  $j$ . As mentioned previously, the *ESE* functions introduced by Krasko [3] were derived in the spirit of EAM, which is relative to the free atom electron density at the impurity site due to the host atoms  $\rho_j^H$ , while the host atom embedded functions are expressed relative to the effective atomic density,  $\rho_i^h$ . To avoid possible confusion relative to the meaning of the density functions used, the *ESE* functions were rederived in this report relative to the effective atomic density used by Finnis and Sinclair,  $\rho_i^h$ . The resulting *ESE* ( $\rho^{\text{imp}}$ ) expressed as fourth-order polynomials are given as:

$$ESE(\rho^{\text{imp}}) = \sqrt{\rho^{\text{imp}}} \left( C_0 + C_1 \rho^{\text{imp}} + C_2 (\rho^{\text{imp}})^2 + C_3 (\rho^{\text{imp}})^3 \right). \quad (8)$$

The values of the coefficients  $C_0$ ,  $C_1$ ,  $C_2$ , and  $C_3$  for various impurities and microalloying additions are given in Table 1, and the corresponding *ESE* vs.  $\rho^{\text{imp}}$  functions are plotted in Figure 1.

**Table 1. ESE Energy vs. Effective Atomic Density,  $\rho$ , Function Coefficients for Various Impurities in W**

$ESE \text{ (eV)} = \sqrt{\rho} (C_0 + C_1 \rho + C_2 \rho^2 + C_3 \rho^3)$

**Figure 1. ESE Energy vs. Atomic Electron Density Functions for Various Grain-Boundary Impurities and Microalloying Additions in W.**

## 2.2. Computational Crystal.

**2.2.1 Generation of the Grain Boundary.** Simulations were carried out using a cylindrical crystal whose crystallographic orientation is shown in Figure 2. The dimensions of the crystal are given in terms of the number of  $(\bar{1}\bar{1}2)$ ,  $(111)$ ,  $(\bar{1}10)$  bcc interplanar spacings along the three principal axes. The initial diameter of the crystal was approximately 9 nm.

To generate a  $\Sigma 3$  (111) grain boundary, the atoms in the upper part of the computational crystal ( $x_2 > 0$ ) were rearranged to produce a configuration that is a mirror image of the lower part of the crystal across the grain boundary plane ( $x_2 = 0$ ). The resulting structure of the computational crystal can be represented by succession of the (111) bcc planes as:

$$C B A C B A C B A B C A B C A B C,$$

where the grain boundary is marked by A. This grain boundary is of a tilt type and is characterized by an inverse coincidence lattice number  $\Sigma = 3$ . Krasko [3] showed that, due to the

**Figure 2. Schematic, Size, and the Crystallographic Orientation of the Computational Crystal Used in the Present Work.**

associated lowest energy level, an impurity atom such, as B, C, N, etc., is most likely to occupy an interstitial position in the center of the trigonal prism formed by 6 W atoms in the  $\Sigma 3$  (111) grain boundary. Consequently, all the simulations of the  $\Sigma 3$  (111) grain boundary containing impurities were done under the condition that the impurity atoms occupy the interstitial sites associated with the trigonal prisms along the grain boundary plane. Note that for a typical grain size range of 10–100  $\mu\text{m}$ , the introduction of interstitials into every grain boundary interstitial site corresponds to the impurity concentration range of 80–20 ppm.

**2.2.2 Grain Boundary Crack.** To generate a crack along the  $\Sigma 3$  (111) grain boundary, all the atoms in the computational crystal were displaced from their initial positions in accordance with the plane strain linear elastic solution developed by Sih and Liebowitz [16] for the crack displacements in an anisotropic single crystal. While, in general, the single-crystal solution of Sih and Liebowitz [16] is not valid for interfacial cracks, the fact that the two crystals in Figure 2 had identical corresponding crystallographic directions in the three principal directions justifies the use of this plane strain procedure. Under a pure tensile load applied in the  $x_2$  direction and for plane strain condition along the  $x_3$  direction, the components of the displacement along the three principal axes are given as follows:

$$\begin{aligned}
u_1 &= K_I \sqrt{\frac{2r}{\pi}} \operatorname{Re} \left\{ \frac{1}{S_1 - S_2} \times [s_1 p_2 (\cos \theta + s_2 \sin \theta)^{1/2} \right. \\
&\quad \left. - s_2 p_1 (\cos \theta + s_1 \sin \theta)^{1/2}] \right\} \\
u_2 &= K_I \sqrt{\frac{2r}{\pi}} \operatorname{Re} \left\{ \frac{1}{S_1 - S_2} \times [s_1 q_2 (\cos \theta + s_2 \sin \theta)^{1/2} \right. \\
&\quad \left. - s_2 q_1 (\cos \theta + s_1 \sin \theta)^{1/2}] \right\} \\
u_3 &= 0,
\end{aligned} \tag{9}$$

where  $r$  and  $\theta$  are the polar coordinates, i.e., the radial distance and the angle between the radial line and the  $x_1$ -axis in Figure 2. Functions  $p_j$  and  $q_j$  ( $j = 1, 2$ ) are defined as:

$$\begin{aligned}
p_1 &= a_{11}s_1^2 + a_{12} - a_{16}s_1 \\
p_2 &= a_{11}s_2^2 + a_{12} - a_{16}s_2 \\
q_1 &= \frac{a_{12}s_1^2 + a_{22} - a_{26}s_1}{s_1} \\
q_2 &= \frac{a_{12}s_2^2 + a_{22} - a_{26}s_2}{s_2},
\end{aligned} \tag{10}$$

where  $s_1 = \mu_1 \alpha_1 + i\beta_1$  and  $s_2 = \mu_2 \alpha_2 + i\beta_2$  are two noncomplex conjugate roots of the following characteristic equation:

$$a_{11} \mu_j^4 - 2a_{16} \mu_j^3 + (2a_{12} + a_{66}) \mu_j^2 - 2a_{26} \mu_j + a_{22} = 0. \tag{11}$$

The remaining two solutions of equation (11) are the corresponding complex conjugates of the first two, i.e.,  $\mu_3 = \mu_1^*$  and  $\mu_4 = \mu_2^*$ .  $a_{ij}$  coefficients appearing in equations (10) and (11) are related to the elastic compliance constants of the material,  $S_{ij}$  and for plane-strain are given as:

$$\begin{aligned}
a_{11} &= \frac{S_{11}S_{33} - S_{13}^2}{S_{33}}, \quad a_{12} = a_{21} = \frac{S_{12}S_{33} - S_{13}S_{23}}{S_{33}}, \\
a_{22} &= \frac{S_{22}S_{33} - S_{23}^2}{S_{33}}, \quad a_{16} = a_{61} = \frac{S_{16}S_{33} - S_{13}S_{36}}{S_{33}}, \\
a_{66} &= \frac{S_{66}S_{33} - S_{36}^2}{S_{33}}, \quad a_{26} = a_{62} = \frac{S_{26}S_{33} - S_{13}S_{36}}{S_{33}}.
\end{aligned} \tag{12}$$

For a given material, the elastic compliance constants used in equation (12) depend on the crystallographic orientation of the computational crystal being examined. Parameter  $K_I$  appearing in equation (10) is the mode I stress intensity factor whose critical value associated with the reversible crack extension, the Griffith stress intensity factor,  $K_{Gr}$ , is given as [16]:

$$K_{Gr} = \sqrt{2\gamma_{sep}/A}, \tag{13}$$

where  $A$  is defined as:

$$A = \left\{ \left( \frac{a_{11}a_{22}}{2} \right) \left[ \left( \frac{a_{22}}{a_{11}} \right)^{1/2} + \frac{2a_{12} + a_{66}}{2a_{11}} \right] \right\}^{1/2}, \tag{14}$$

and this parameter also in the relationship between the  $J_I$ -integral and the stress intensity factor  $K_I$ ,  $J_I = AK_I^2$  by Sih and Liebowitz [16]. The  $2\gamma_{sep}$  term appearing in equation (13) represents the ideal work of grain boundary separation and is equal to the amount by which the work per unit area of the crack surface done by the external loads exceeds the change in the elastic strain energy. At the onset of crack growth,  $2\gamma_{sep}$  is given as:

$$2\gamma_{sep} = \gamma_s^A + \gamma_s^B - \gamma_{int}^{AB}, \tag{15}$$

where superscripts A and B denote the two crystals being jointed along the grain boundary,  $\gamma_s$  is the surface energy, and  $\gamma_{int}$  the grain boundary (interface) energy.

**2.3 Computation of the Ideal Work of Grain Boundary Separation,  $2\gamma_{\text{int}}$ .** To compute the surface energy associated with the  $(111)_{\text{bcc}}$  crystallographic plane, the crack plane, a rectangular slab with the same orientation as the computational crystal shown in Figure 2 and with its top and bottom surfaces parallel to this plane, is created. The height of the crystal is chosen to be large enough to avoid the interaction between the top and the bottom surfaces. With the periodic boundary conditions applied in the other two orthogonal directions, the energy of the slab is minimized. The surface energy is then defined as the excess energy per unit surface area of this crystal, relative to the one of the same size in which the periodic boundary conditions are applied in all three directions.

The previous procedure is repeated using a slab containing the  $\Sigma 3$   $(111)$  grain boundary and the corresponding grain boundary energy calculated as the excess energy of the slab per unit grain boundary area relative to the perfect bcc without a grain boundary subject to the periodic boundary condition in all the directions.

The same procedure for calculating the surface and the grain boundary energy was utilized for the cases where the initial grain boundary contains one of the impurities or microalloying additions. The results of the previous procedure for pure W and W containing impurities are summarized in Table 2.

**2.4 Molecular Dynamics Method.** The evolution of the material surrounding the crack tip is studied using the standard molecular dynamics procedure at 100 K. The molecular dynamics calculations involve the solution of the Newton equations of motion for a system of interacting particles (atoms) in order to determine the classical particle trajectories and velocities.

At the beginning of each simulation run, a crack was generated by displacing all atoms according to equation (9) from their initial positions corresponding to the perfect unrelaxed bcc bicrystal structure shown in Figure 2. All the molecular dynamics simulation runs were done under the fixed periodic boundary conditions in the  $x_3 = [110]_{\text{bcc}}$  direction to ensure the plane strain condition in this direction. Also, at each level of  $K_I$ , fixed displacement boundary conditions were applied onto the outer surface of the computational crystal.

**Table 2. (111)<sub>bcc</sub> Surface Energy,  $\gamma_{\text{surf}}$ ,  $\Sigma 3$  (111)<sub>bcc</sub> Grain Boundary Energy,  $\gamma_{\text{GB}}$ , and the Corresponding Ideal Work of Grain Boundary Decohesion,  $2\gamma_{\text{int}}$ , for W Containing Various Impurities**

Si	0.1925	0.3074	0.3136
S	0.0735	0.3515	0.1505
P	0.1100	0.3275	0.2110

The temperature at which all the simulation runs were carried out, 100 K, was set by initially assigning to each atom a random velocity according to the Boltzmann distribution. During the simulation process, the temperature was maintained constant by exponentially relaxing, at each time step (2 fs), the average squared atomic velocity using a time constant of 0.1 ps. Using this procedure, the temperature could be maintained with 3% of its target value.

**2.5 Computation of  $F_1$  Integral.** To quantify the effect of the crack-tip stress relaxation processes on the resistance of a  $\Sigma 3$  (111) grain boundary to separation, Eshelby's conservation  $F$  integral [17] was calculated for both the pure W case and the cases of W containing one of the impurities or microalloying additions. The  $F$  integral provides a means for determination of the energy release rate accompanying the crack extension in cases where material nonlinearity effects cannot be neglected.  $F$  is a vector, and its components along the three principal axes (the cracking direction  $x_1$ , the crack plane normal direction  $x_2$ , and the crack front direction  $x_3$ ) represent the three force components acting on the crack tip. For the computational crystal and the crack orientation used in the present work (Figure 2),  $F_1$  acts to propagate the crack tip, while  $F_2$  and  $F_3$  are not physical. The components of  $F$  can be defined using a closed contour  $\Gamma$ , which surrounds the crack tip as follows [17]:

$$F_i = \int_r \left[ W \gamma_{ij} - \sigma_{kj} \frac{\partial u_k}{\partial x_i} \right] dS_j, \quad (16)$$

where  $W$  is the strain energy density,  $u_k(x_i)$  is the  $k$ -component ( $k = 1,2,3$ ) of the displacement at a point represented by the coordinates  $x_i$  ( $i = 1,2,3$ ),  $\sigma_{ij}$  are the stress components, and  $dS_j = dS n_j$ , where  $n_j$  is the  $j$  component ( $j = 1,2,3$ ) of the unit outward normal vector to the contour segment of length  $dS$ . To calculate the stresses, the procedure proposed by Hoagland, Daw, and Hirth [18] was used. According to this procedure, the strain energy density associated with an atom at the position  $x_i$  is defined as:

$$W(x_i) = \frac{E(x_i) - E_0}{\Omega_0}, \quad (17)$$

where  $E(x_i)$  is the potential energy of the atom with the coordinates  $x_i$  ( $i = 1,2,3$ ),  $E_0$  is the equilibrium energy, which the atom would have in a perfect, stress-free bulk crystal, and  $\Omega_0$  is the equilibrium atomic volume. The energies  $E(x_i)$  and  $E_0$  are calculated using the Finnis-Sinclair interatomic potential and an energy expression for the potential per atom analogous to equation (1). Assuming that for small strain increments the strain energy density can be approximated as being quadratic in incremental strains, the stresses are calculated using the following central difference formula:

$$\sigma_{ij} = \frac{\partial W}{\partial \epsilon_{ij}} = \frac{W(x_i + \delta_i) - W(x_i - \delta_i)}{2\Delta u_{ij}}, \quad (18)$$

where  $\epsilon_{ij}$  are the components of the strain tensor and  $\delta_i = u_{ij}x_j$  is a small perturbation of the atomic position, which is the result of the application of a small uniform displacement gradient  $\Delta u_{ij}$  to the entire crystal. The value of  $\Delta u_{ij} = 0.0005$  was found to be optimal in the present work. To compute the components of the stress, one of the  $\Delta u_{ij}$  is set to 0.0005 at a time (the other  $\Delta u_{ij}$  are kept at zero) and corresponding nonzero  $\delta_i$  computed and used in equation (18).

From the theory of elasticity, it is known that the distortions  $u_{ij} = \partial u_i / \partial x_j$  are composed of strain ( $\epsilon_{ij}$ ) and rotational ( $w_{ij}$ ) components, i.e.,  $u_{ij} = \epsilon_{ij} + w_{ij}$ . A strain ellipsoid that relates the extensional strain between an atom and its  $\alpha$ -th neighbor:  $\epsilon^\alpha = (r^\alpha/R^\alpha) - 1$ , where  $r^\alpha$  and  $R^\alpha$  are respectively the atomic distances after and before straining, can be used to obtain the local strain components  $\epsilon_{ij}$  as follows:

$$\epsilon^\alpha = l_i^\alpha l_j^\alpha \epsilon_{ij}, \quad (19)$$

where  $l_i^\alpha$  are the directional cosines (in the unstrained lattice) to  $\alpha$  atom. Equation (19) simply represents a transformation of the strain components from the coordinate system given in Figure 2 to the one whose  $x_1$  axis is along the line connecting the two atoms in question, i.e., the atom at whose location the strain components are being evaluated and its  $\alpha$ -neighbor. To find the strain components  $\epsilon_{ij}$  at the position of an atom, a least-squares procedure was used to minimize the following sum over the  $n$  neighbors of each atom:

$$L_\epsilon = \sum_{\alpha=1}^n (\epsilon^\alpha - l_i^\alpha l_j^\alpha \epsilon_{ij})^2. \quad (20)$$

The minimization procedure  $\partial L_\epsilon / \partial \epsilon_{ij} = 0$ , yields six linear algebraic (normal) equations, which were readily solved using the Gauss elimination method [19]. The basis for determination of rigid body rotations,  $w_{ij}$ , at a particular site is obtained by proceeding in a manner similar to the one employed for the strains. The relationship between displacements of the nearest neighbors from the given atom,  $u_i^\alpha$ , and the antisymmetric matrix of the local rotations suggests that the following sum should be minimized:

$$L_R = \sum_{\alpha} \left[ (u_1^\alpha + w_{12}x_2^\alpha - w_{13}x_3^\alpha)^2 + (u_2^\alpha - w_{12}x_1^\alpha + w_{23}x_3^\alpha)^2 + (u_3^\alpha + w_{13}x_1^\alpha - w_{23}x_2^\alpha)^2 \right]. \quad (21)$$

The minimization procedure  $\partial L_R / \partial w_{ij} = 0$  yields three normal equations, which were also readily solved using the Gauss elimination method. The evaluation of the  $F_1$  integral given by equation (16) was done numerically in the present work using the trapezoidal rule [19] along a circular contour around the crack. Owing to the discrete nature of the crystal, all the atoms within a distance of 0.2 nm from the contour were assumed to be associated with the contour. The magnitude of the contour segment  $dS^\alpha$  corresponding to an atom  $\alpha$  is calculated as  $dS^\alpha = R(\theta_{\alpha+1} - \theta_{\alpha-1})/2$ , where  $R$  is the contour radius and  $\theta_{\alpha+1}$  and  $\theta_{\alpha-1}$  are, respectively, the polar angles for the atoms in the contour that immediately follow and precede atom  $\alpha$  in the counterclockwise direction. The unit vector normal  $n^\alpha$  to the contour segment  $dS^\alpha$ , where  $i$  and  $j$  are the unit vectors in  $x_1$  and  $x_2$  directions, is defined as  $n^\alpha = \cos \theta_\alpha i + \sin \theta_\alpha j$ , respectively [20].

Note that the strain energy density  $W$  and, hence,  $F_1$  each have two contributions: one associated with the strain energy density, and the other arising from the work of grain boundary separation. The former contribution to  $F_1$  and  $J_1$  integral acts to extend, while the latter,  $2\gamma_{sep}$ , acts to close the crack. Hence, the following relationship holds:

$$F_1 = J_1 - 2\gamma_{sep}. \quad (22)$$

### 3. Results and Discussion

**3.1 Ideal Work of Grain Boundary Decohesion.** The results of our calculation of the (111) surface energy,  $\Sigma 3$  (111) grain boundary energy, and of the corresponding work of grain boundary decohesion are listed in Table 2. The results pertain to the case when, after decohesion, all the impurity atoms remain on one of the crack faces and the other crack face is clean of impurities. While the magnitudes of the work of separation take on different values when the impurities are assumed to divide equally between the two crack surfaces (data not shown), the general findings regarding the effect of various grain boundary impurities on the grain boundary decohesion resistance remain. The results shown in Table 2 indicate that, on the one hand, elements such as B, C, and N increase the work of  $\Sigma 3$  (111) grain boundary decohesion. On the other hand, elements such as O, Al, and Si have a relatively small effect on

this work. Lastly, elements such as P and S act as strong grain boundary embrittlers and reduce this work. These findings are further correlated with the grain boundary energy data shown in Table 2. The grain boundary energy data show that B, C, and N reduce the grain boundary energy the most, while P and S reduce this energy the least. This suggests that B, C, and N would, via the site-competition effect, tend to displace P and S from the grain boundary and, in turn, enhance the grain boundary cohesion. In other words, the deleterious embrittling effect of impurities such as P and S in W can be, as previously suggested by Krasko [3], reduced by using microalloying additions of microalloying elements such as B, C, and N.

**3.2 Initial Atomic Configurations.** The initial atomic configuration of the  $\Sigma 3$  (111) grain boundary in pure W ("clean" grain boundary) containing a crack at the applied stress intensity factor  $K_{app} = 2.0 K_{Gr} = 2.7694 \text{ MPa m}^{1/2}$  and the corresponding configurations after relaxation (energy minimization) are shown in Figure 3(a) and Figure 3(b), respectively. The energy minimization was carried out using the conjugate gradient method [21]. The structure of the grain boundary ahead of the crack after relaxation can be characterized by analyzing the spacing of the adjacent (111) planes as a function of the distance from the grain boundary and comparing it with the bulk value in pure W,  $d_{(111)} = 0.9137 \text{ \AA}$ . As shown in Table 3, the (111) interplanar spacing oscillates with the distance from the grain boundary with the amplitude of oscillations gradually decreasing. Consequently by the 10–12th plane away from the grain boundary (not shown in Table 3), the oscillations are practically damped out. The results shown in Table 3 correspond to the average (111) interplanar spacings at a distance between 16.9 and 19.6  $\text{\AA}$  from the crack tip in the positive  $x_1$  direction. It should be noted that the distance between the second and the third plane has decreased significantly relative to that in the bulk bcc W. This behavior is the manifestation of the crystal's tendency to reduce the free-volume of the grain boundary. Also note that because the plane of the crack lies between the grain boundary plane and the first (111) plane below the grain boundary plane, the variation of the (111) interplanar spacing with the distance from the grain boundary is different for the (111) planes below and above the grain boundary plane.

The initial atomic configuration of the  $\Sigma 3$  (111) grain boundary with a crack in W containing B impurity atoms located in trigonal interstitial sites and the corresponding configuration after

**Figure 3. Initial Atomic Configuration of the “Clean”  $\Sigma 3$  (111) Grain Boundary in W Containing a Crack: (a) Before Relaxation, and (b) After Relaxation. The Applied Level of the Stress Intensity Factor  $K_{app} = 2.0 K_{Gr} = 2.7694 \text{ MPa m}^{1/2}$ .**

**Table 3. The Spacing, in Å, Between Two Adjacent (111) Planes as a Function of the Distance From the Grain Boundary in Pure W and in W Containing B and P Grain Boundary Impurities**

Adjacent (111) Planes	Type of Grain Boundary		
	Clean	With B	With P
Above the Grain Boundary Plane			
G.B. Plane-Plane 1	1.292	1.334	1.555
Plane 1-Plane 2	0.609	0.801	0.906
Plane 2-Plane 3	1.009	0.828	0.734
Plane 3-Plane 4	0.984	0.987	0.977
Plane 4-Plane 5	0.824	0.865	0.906
Below the Grain Boundary Plane			
G.B. Plane-Plane 1	1.252	1.338	1.570
Plane 1-Plane 2	0.566	0.808	0.908
Plane 2-Plane 3	1.051	0.830	0.734
Plane 3-Plane 4	0.973	0.987	0.968
Plane 4-Plane 5	0.821	0.863	0.917

energy minimization are shown in Figure 4(a) and Figure 4(b), respectively. The relaxed configurations for the same type of grain boundary containing other grain boundary cohesion enhancers such as C and N are quite similar to the one shown in Figure 4(b) and are not shown here for brevity. The variation of the (111) interplanar spacings with distance from the grain boundary for the relaxed configuration depicted in Figure 4(b) is listed in Table 3. In comparison with the “clean” grain boundary beyond the two planes adjacent to the grain boundary plane, the magnitudes of the oscillation amplitude of the (111) interplanar spacings are significantly lower. In addition, the distance of the two nearest (111) and the two next-nearest (111) planes to the grain boundary increase somewhat due to the presence of interstitial impurities of B, C, or N relative to those in the case of clean grain boundary in W, Table 3.

**Figure 4. Initial Atomic Configuration of the  $\Sigma 3$  (111) Grain Boundary in W Containing a Crack With B Atoms (Smaller Balls) Located in Trigonal Interstitial Grain Boundary Sites: (a) Before Relaxation, and (b) After Relaxation. The Applied Level of the Stress Intensity Factor  $K_{app} = 1.4 K_{Gr} = 2.9548 \text{ MPa m}^{1/2}$ .**

The initial atomic configuration of the  $\Sigma 3$  (111) grain boundary with a crack in W containing phosphorus impurity atoms located in trigonal interstitial sites and the corresponding configuration after energy minimization are shown in Figure 5(a) and Figure 5(b), respectively. The relaxed configuration for the same type of grain boundary containing other grain boundary embrittlors such as S is quite similar to the one shown in Figure 5(b) and is not shown here for brevity. The variation of the (111) interplanar spacings with distance from the grain boundary

**Figure 5. Initial Atomic Configuration of the  $\Sigma 3$  (111) Grain Boundary in W Containing a Crack With P Atoms (Smaller Balls) Located in Trigonal Interstitial Grain Boundary Sites: (a) Before Relaxation, and (b) After Relaxation. The Applied Level of the Stress Intensity Factor  $K_{app} = 1.2 K_{Gr} = 1.4563 \text{ MPa m}^{1/2}$ .**

for the relaxed configuration depicted in Figure 5(b) is listed in Table 3. In comparison with the “clean” grain boundary, the magnitudes of the oscillation amplitude are significantly larger. Furthermore, the distance of the two nearest and the two next-nearest (111) planes from the grain boundary is significantly increased relative to those observed in the cases of the clean grain boundary and the grain boundary containing B, C, or N impurities.

**3.3 Material Evolution at the Crack Tip.** The progress of material evolution at the crack tip in the case of a clean  $\Sigma 3$  (111) grain boundary at the applied stress intensity factor  $K_{app} = 2.7694 \text{ MPa m}^{1/2}$  is shown in Figure 6(a) and Figure 6(b). This level of the applied  $K_I$  is the minimal level at which a clear evidence of crack propagation by 0.5 ps of the molecular dynamics simulation time can be obtained. A comparison of the atomic configuration after 0.5 ps simulation time, Figure 6(a), with the original configuration, Figure 3(a), shows a significant rearrangement of the atoms in the region surrounding the crack tip. This rearrangement leads to a significant crack blunting. No evidence of dislocation emission from the crack tip can be found. Atomic rearrangement with a small additional crack blunting continues to take place with

**Figure 6. Atomic Configuration of the  $\Sigma 3$  (111) “Clean” Grain Boundary in W After the Molecular Dynamics Simulation Times: (a) 0.5 ps, and (b) 5 ps. The Applied Stress Intensity Factor  $K_{app} = 2.0 K_{Gr} = 2.7694 \text{ MPa m}^{1/2}$ .**

the simulation time, which can be readily established by analyzing the atomic configuration after 5 ps, Figure 6(b). It is interesting to note that as a result of the aforementioned material evolution, a one-atom thick, one-lattice parameter-wide strip of the  $(110)_{bcc}$  plane has formed at the very crack tip, Figure 6(b). This plane is normal to the original crack plane, (111), and a  $[100]$  direction in this plane is aligned with the initial crack front-direction  $[\bar{1}10]$ . The formation of this strip not only causes additional crack blunting but also changes the local ideal work of grain boundary decohesion, which in this case can be approximated as  $2\gamma_{surf}^{(100)}$ , where  $\gamma_{surf}^{(100)}$  is the surface energy of the (100) plane. Using the aforementioned procedure for the calculation of the surface energy, the ideal work of grain boundary decohesion has been determined as  $2\gamma_{surf}^{(100)} = 0.8128 \text{ eV/\AA}^2$ . Since this value is higher than the one  $0.2747 \text{ eV/\AA}^2$  reported previously in Table 2, this may be the reason why crack propagation stops once the (110) strip forms at the grain boundary.

The material evolution in the region surrounding the crack tip in the cases of the  $\Sigma 3$  (111) grain boundary containing interstitially dissolved O, Al, or S atoms is quite similar to that of the clean grain boundary and will not be discussed any further.

The progress of material evolution at the crack tip in the case of  $\Sigma 3$  (111) grain boundary containing interstitially dissolved B atoms at the applied stress intensity factor  $K_{app} = 1.6 K_{Gr} = 3.3770 \text{ MPa m}^{1/2}$  is shown in Figure 7(a) and Figure 7(b).  $K_I = 0.8 K_{Gr} = 1.6885 \text{ MPa m}^{1/2}$  is the minimal  $K_I$  value at which a noticeable crack advancement could be found by 0.5 ps of the molecular dynamics simulation time. A comparison of the atomic configuration after 0.5 ps simulation time, Figure 7(a), with the corresponding original configuration, Figure 4(a), shows that a significant material evolution takes place in the region surrounding the crack tip. This evolution gives rise to a major crack tip blunting, but no evidence of dislocation emission can be found. The aforementioned material evolution and the accompanying crack-tip blunting continues with the simulation time, Figure 7(b). It is also important to note that after 5 ps, Figure 7(b), B atoms form a cluster at the crack tip. This cluster is expected to enhance the intergrain bonding and, in turn, the ideal work of work of grain boundary decohesion. This may be the reason why once the cluster of B atoms is formed, the crack propagation ceases.

**Figure 7. Atomic Configuration of the  $\Sigma 3$  (111) “Clean” Grain Boundary in W After the Molecular Dynamics Simulation Times: (a) 0.5 ps, and (b) 5 ps. The Applied Stress Intensity Factor  $K_{app} = 1.6 K_{Gr} = 3.3770 \text{ MPa m}^{1/2}$ .**

The progress of material evolution at the crack tip in the case of the  $\Sigma 3$  (111) grain boundary containing interstitially dissolved P atoms at the applied stress intensity factor  $K_{app} = 1.2 K_{Gr} = 1.4563 \text{ MPa m}^{1/2}$  is shown in Figure 8(a) and Figure 8(b).  $K_I = 0.4 K_{Gr} = 0.4854 \text{ MPa m}^{1/2}$  is

**Figure 8. Atomic Configuration of the  $\Sigma 3$  (111) Grain Boundary in W Containing Phosphorous Atoms (Smaller Balls) After the Molecular Dynamics Simulation Times: (a) 0.5 ps, and (b) 5 ps. The Applied Stress Intensity Factor  $K_{app} = 1.2 K_{Gr} = 1.4563 \text{ MPa m}^{1/2}$ .**

the minimal value of the stress intensity factor at which a noticeable crack extension could be observed by 0.5 ps of the simulation time. A comparison of the atomic configuration after 0.5 ps of the simulation time, Figure 8(a), with the corresponding initial configuration, Figure 5(a), shows that a significant rearrangement of the atoms takes place in the region of the grain boundary ahead of the crack. This evolution causes a significant increase in the interatomic distances in the grain boundary region. This, however, does not cause any crack tip blunting, and the crack tip remains as sharp as in the original configuration. The aforementioned material evolution continues with the simulation time, and after 5 ps, Figure 8(b), the crack tip has advanced by approximately  $17 \text{ \AA}$  relative to its original position. If the simulation time is increased beyond 5 ps, the crack continues to advance until it reaches fixed atoms at the outer rim of the computational crystal.

**3.4 Mechanics of Grain Boundary Fracture.** To quantify the effect of the various material evolution processes described in the previous section on the intrinsic resistance of the  $\Sigma 3$  (111) grain boundary in pure W and in W containing different impurities microalloying additions, the Eshelby  $F_1$  conservation integral was calculated. As discussed previously,  $F_1$  represents the

force acting on the crack tip in the  $x_1$  direction. The time evolution of this force whose initial value corresponds to the minimal level for the applied stress intensity factor at which a noticeable crack advance could be seen by 0.5 ps simulation time is given in Table 4 and plotted in Figure 9.

**Table 4. The Stress Intensity Factor for a Reversible Extension of the Grain Boundary Crack,  $K_{Gr}$  [Equation (12)], the Critical Stress Intensity Factor for Crack Extension Obtained During Molecular Dynamics Simulations,  $K_{crit}$ , and the Corresponding Value of the Eshelby's  $F_1$  Conservation Integral**

Impurity	$K_{Gr}$ (MPa m <sup>1/2</sup> )	$K_{crit}$ (MPa m <sup>1/2</sup> )	$F_1$ (eV/Å <sup>2</sup> )		
			0 ps	0.5 ps	1.0 ps
Pure W	1.3847	1.6616	1.0953	0.8397	0.8256
B	2.1106	1.6885	1.4431	0.6313	0.6095
C	2.0587	1.8528	1.4006	0.6127	0.5913
N	2.0337	1.9320	1.3836	0.6053	0.5841
O	1.4781	1.4781	1.0055	0.4424	0.4269

Si	1.4795	0.5918	1.0066	0.3857	0.3722
S	1.0249	0.4100	0.6973	0.5051	0.4944
P	1.2136	0.4854	0.8257	0.6612	0.5485

**Figure 9. Time Dependence of the  $F_1$  Integral.**

In each of the cases analyzed, a positive value of  $F_1$  is required to initiate crack propagation. It appears that the initial values of  $F_1$  fall into three groups: the highest values ( $F_1 \approx 1.4 \pm 0.1 \text{ eV/\AA}^2$ ) for the  $\Sigma 3$  (111) grain boundary containing interstitially dissolved B, C, or N atoms; the intermediate value ( $F_1 \approx 1.0 \pm 0.1 \text{ eV/\AA}^2$ ) for the clean  $\Sigma 3$  (111) grain boundary, and the one containing dissolved O, Al, or Si atoms and the lowest value ( $F_1 \approx 0.7 \pm 0.1 \text{ eV/\AA}^2$ ) for the grain boundary containing P or S impurities. These findings are fully consistent with the results for the ideal work of grain boundary decohesion listed in Table 2.

Figure 9 further shows that, as the simulation time increases, the aforementioned material evolution at the crack tip continues to take place, and, as a result, the magnitude of the crack tip decreases. This decrease between 0 and 1 ps is significant in all the cases except for the ones involving interstitially dissolved P and S atoms at the grain boundary where the decrease in  $F_1$  with the simulation time is quite small. Past 1 ps no major change in the magnitude of  $F_1$  is found. In other words, the material evolution at the crack tip causes  $F_1$  to decrease by only a lower positive value. In the cases of the clean  $\Sigma 3$  (111) grain boundary and such a boundary containing B, C, N, O, Al, or Si, this lower level of  $F_1$  is not sufficient to give rise to any additional crack extension, and consequently, the crack growth ceases. In sharp contrast, when the grain boundary contains P and S impurities, the crack growth continues while the  $F_1$  remains fairly constant. The continued crack growth in the case of the grain boundary containing P and S atoms is promoted by a continued rearrangement of the grain boundary atoms, which causes an increase in the interatomic distances. In other words, the atomic density in the grain boundary region continues to decrease and, in turn, lowers the cohesion strength of the grain boundary.

In summary, the atomic simulation results obtained in the present work confirm, as has been observed experimentally, that the fracture toughness of W is affected greatly by the type of impurities segregated to its grain boundaries. Note, however, that in the present work only cases of clean grain boundaries and boundaries fully saturated with a single species are considered. When two or more impurity species are present, Krasko [3] showed that the one whose energy at the grain boundary is lower will preferentially segregate to the grain boundary and, thus, have the dominant effect on materials fracture toughness. In the few simulations in which partially contaminated grain boundaries (i.e., the grain boundary was not fully saturated with impurities)

were used, we observed that the character of the effect (embrittling or cohesion enhancing) did not change but its magnitude was lower.

Note that our results differ somewhat from the findings of Krasko [3]. Specifically, N was identified by Krasko [3] as a grain boundary embrittler, while in the present work, this element was found to be a cohesion enhancer. Furthermore, O, Al, and Si were identified by Krasko [3] as grain boundary embrittlors while these elements were found to be neutral in the present work. As far as H is concerned, the embedded energy functions for this element were not available and its effect on grain boundary cohesion could not be studied. We believe that the differences between the results obtained by Krasko [3] and our results stem from the differences in the simulation methods used—Krasko [3] applied molecular statics and constrained the motion of atoms to the planes parallel to the grain boundary. This constraint was lifted in the present work, and the simulations were carried out using molecular dynamics. This method allows the atoms to relax into the configuration associated with a lower energy and is generally considered as a more appropriate simulation method for nonzero temperatures.

## 4. Conclusions

Based on the results obtained in the present work, the following main conclusions can be drawn:

- (1) With respect to their effect on the intrinsic fracture resistance of the  $\Sigma 3$  (111) grain boundary in W, the atomic species analyzed can be divided into three groups:
  - (a) Interstitially dissolved B, C, and N are strong grain boundary cohesion strengtheners, which both enhance intergrain bonding and give rise to a lower level of effective loading at the crack tip by promoting crack tip blunting. There is some evidence that clustering of the interstitial atoms is, at least partly, responsible for the observed fracture resistance.

- (b) O, Al, and Si do not significantly affect either the ideal work of grain boundary decohesion or the crack blunting processes relative to those observed in the case of the clean  $\Sigma 3$  (111) grain boundary.
  - (c) P and S are strong grain boundary embrittlors that both significantly lower the ideal work of grain boundary decohesion and impede with crack tip blunting processes.
- (2) Regardless, whether the intrinsic fracture of the  $\Sigma 3$  (111) grain boundary is measured using the ideal work of grain boundary decohesion or by the critical value of the  $F_1$  integral, removal of deleterious impurities, such as P or S, by either material purification or by the site competition effect with B, C, or N can have a great potential in achieving the goal of producing the "ductile" W.

13. ABSTRACT (Maximum 200 words) The effect of various impurities and micro-alloying additions (B, N, C, O, Al, Si, S, and P) on the intrinsic resistance of the $\Sigma 3$ (111) grain boundary in tungsten has been investigated using the molecular dynamics simulation. The atomic interactions have been accounted for through the use of Finnis-Sinclair interatomic potentials. The fracture resistance of the grain boundary has been characterized by computing, in each case, the ideal work of grain boundary separation, the mode I stress intensity factor, and the Eshelby's $F_1$ conservation integral at the onset of crack propagation. The results obtained suggest that pure tungsten is relatively resistant to grain boundary decohesion and that this resistance is further enhanced by the presence of B, C, and N. Elements such as O, Al, and Si, however, have a relatively minor effect on the cohesion strength of the $\Sigma 3$ (111) grain boundary. In sharp contrast, S and P greatly reduce this strength, making the tungsten quite brittle. These findings have been correlated with the effect of the impurity atoms on material evolution at the crack tip.

## USER EVALUATION SHEET/CHANGE OF ADDRESS

This Laboratory undertakes a continuing effort to improve the quality of the reports it publishes. Your comments/answers to the items/questions below will aid us in our efforts.

1. ARL Report Number/Author ARL-TR-2051 (Grujicic [POC: Alder]) Date of Report September 1999

2. Date Report Received \_\_\_\_\_

3. Does this report satisfy a need? (Comment on purpose, related project, or other area of interest for which the report will be used.) \_\_\_\_\_  
\_\_\_\_\_  
\_\_\_\_\_

4. Specifically, how is the report being used? (Information source, design data, procedure, source of ideas, etc.) \_\_\_\_\_  
\_\_\_\_\_  
\_\_\_\_\_

5. Has the information in this report led to any quantitative savings as far as man-hours or dollars saved, operating costs avoided, or efficiencies achieved, etc? If so, please elaborate. \_\_\_\_\_  
\_\_\_\_\_  
\_\_\_\_\_

6. General Comments. What do you think should be changed to improve future reports? (Indicate changes to organization, technical content, format, etc.) \_\_\_\_\_
